If we are building model from scratch by hand, by looking at data we can notice that people above BMI 25 are prone to diabetes so it has a simple decision boundary (above 2 class 1, below 25 class 0) but real data is messy, we will have people with higher bmi but donot have diabetes and vice versa so SVM looks through all the features not only bmi and finds the best decision boundary

Class 1: PRECISION ranges from O to 1. If it is close to 1, our model avoids predicting that people have diabetescif they actually dont. That would be false positive. But precision may be high because we are underestimating how many people are sick.

RECALL: It also ranges from 0 to 1, if its close to 1 our model has correctly predicted that all the people with diabetes do have disease. This is avoiding false negatives.

We need high presision and high recall

F1 SCORE: It combines the two values but focuses on worst of the two. Its kind of pessimistic(worst) average of precision and recall

SUPPORT: It tells how many samples there were of each class.

In this project

- 1. I have loaded a dataset and extracted its features and labels
- 2. Split it into training and test subsets and normalized
- 3. Set up a SVM using best kernel for job and used it to make medical diagnosis
